delivery of drugs to the eye is complicated by the efficient removal mechanisms in the precorneal area which serve to maintain a good refractive surface. The absorption of drugs into the eye requires a prolonged precorneal residence time and good corneal permeation. However, for most drugs corneal permeation is low. Since the precorneal drug concentration acts as the driving force for passive diffusion, the corneal epithelium and conjunctival membranes act as reservoirs for potential absorption into the eye and surrounding structures. The mucus layer covering the cornea and conjunctiva is an important target to improve drug retention by mucoadhesion of a polymer excipient, especially one that specifically attaches to the corneal rather than to conjunctival mucus. The attached polymer-mucin bond can then be used to entrap soluble, colloidal and particulate material on the eye surface. This review includes literature on various temperature, pH, and ion induced in situ-forming polymeric systems used to achieve prolonged contact time of drugs with the cornea and increase their bioavailability.

Keywords: Mucoadhesive polymers, Poloxamer, Xylglucan, Cellulose derivative, Chitosan Gallen gum, Pseudolatexes, Carbomer.

INTRODUCTION

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers; as a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties. The rapid turnover of lacrimal fluid and efficient drainage apparatus profoundly affect the bioavailability of topically applied ophthalmic drugs. The amount of drug reaching the anterior chamber of the eye is dependent on two competing processes: the rate of drug loss from the precorneal area and the rate of drug uptake by the cornea. When an ophthalmic solution is instilled into the lower cul-de-sac, the reflex action of blinking causes a substantial portion of the drop to be lost to the drainage apparatus and some may spill over onto the cheek. Removal of the instilled volume continues until the total tear volume returns to the normal resident volume. A further consideration is the effect of turnover rate of lacrimal fluid on the concentration and amount of drug remaining on the eye. As the precorneal volume (lacrimal and instilled) gets smaller, the turnover rate of lacrimal fluid will have a greater influence on the residual drug concentration. An optimum volume is required to allow the maximum amount of drug to be in contact with the eye for the maximum period of time, with a minimum of drug loss. The precorneal drug concentration acts as a driving force for drug uptake. If this concentration falls below the epithelial surface concentration, drug reflux into the cornea ceases. The rapid clearance from the ocular surface and the relatively slow absorption through the cornea pose significant problems in drug delivery. Only a small fraction of the instilled drug survives the numerous loss processes experienced in the precorneal area and becomes available for absorption into the cornea. In summary, the success of any topical ocular drug delivery system depends on good corneal penetration plus retention at the site of drug absorption. Ophthalmic research has been directed towards improving the topical route of administration, primarily to increase the amount of drug at the site of absorption and to increase its duration of contact with the target site. Several drug delivery systems have been developed in an attempt to increase drug bioavailability including polymeric solutions, ointments, soluble and insoluble inserts, and phase transition systems. Dosage forms that adhere to mucous membranes have been investigated as a method of optimizing drug delivery. It has been proposed that mucoadhesion occurs after wetting of the adhesive surface, by the interpenetration of the adhesive molecules and mucus glycoprotein followed by the formation of secondary chemical bonds. The concept of mucoadhesion in the eye is to seek polymers that will attach to corneal or conjunctival mucin, via non-covalent bonds, and remain in contact with precorneal tissues until mucin turnover causes elimination of the polymer: in other words, the weaker bond is the mucin-mucin bond rather than the mucin-polymer bond. This would substantially improve ocular drugs in terms of ocular drug bioavailability. While several polymers will attach to mucin through both covalent and non-covalent bonds, non-covalent bonding is preferred as the strength of attachment in many cases is sufficiently strong to be considered essentially irreversible. However, if the bond is too strong, the polymer offers resistance to blinking and eye movement and will feel uncomfortable in the eye; an ideal mucoadhesive system for ophthalmic use should exhibit only weak adhesive properties. Mucoadhesive polymers both water-soluble and water-insoluble can be placed in front of the eye and attach to the mucin coating. Water-soluble mucoadhesives slowly dissolve in the tear film whereas water-insoluble...
polymers would be retained until the mucin is replaced (estimated to be 15-20 h in man) or more commonly until the shear force of blinking dislodges the mucoadhesive system. Most water-insoluble mucoadhesive polymers have hydrophilic groups that interact with water molecules and expand the polymer network to a more flexible and mobile state. The stretched and entangled mucoadhesive polymer in contact with the hydrophilic mucus substrate matches its active adhesive sites to those on the substrate to form adhesive bonds. A new approach is to try to combine advantages of both solutions and gels, such as accuracy and facility of administration of the former and prolonged residence time of the latter. Thus in situ hydrogels can be instilled as eye drops and undergo an immediate gelation when in contact with the eye. In situ-forming hydrogels are liquid upon instillation and undergo phase transition in the ocular cul-de-sac to form viscoelastic gel and this provides a response to environmental changes. Three methods have been employed to cause phase transition on the surface: change in temperature, pH, and electrolyte composition (Table 1).

**REVIEW OF PAST WORKDONE ON THE POLYMERS**

Qian Y et al\(^8\), in this study, a thermostensitive in situ gelling vehicle was prepared to increase the precorneal resident time and the bioavailability of methazolamide. The optimum concentrations of poloxamer analogs for the in situ gel-forming delivery system were 21% (w/w) poloxamer 407 and 10% (w/w) poloxamer P188. In vitro release studies demonstrated a diffusion-controlled release of MTA from the poloxamer solutions over a period of 10 hours. In vivo evaluation indicated that the poloxamer solutions had a better ability to retain drug than MTA eyedrops did.

Ammar HO et al\(^9\), utilized Poloxomer 407 with its thermoreversible gelation and surface active properties to formulate a novel dorzolamide hydrochloride in situ gel nanoemulsion (NE) delivery system for oculur use. The optimum formulation of in situ gel NE consisted of Triacetin (7.80%), Poloxamer 407 (13.65%), Poloxamer 188 (3.41%), Miranol C2M (4.55%), and water (70.59%). Biological evaluation of the designed dorzolamide formulation on normotensive albino rabbits indicated that this formulation had better biological performance, faster onset of action, and prolonged effect relative to either drug solution or the market product. The formula showed a superior pharmacodynamic activity compared to the in situ gel dorzolamide eye drops. This indicated the effectiveness of the in situ gel properties of poloxamer 407, besides formulating the drug in an NE form for improving the therapeutic efficacy of the drug.

Cao F et al\(^10\), developed new method for ophthalmic delivery of azithromycin by poloxamer/carbopol-based in situ gelling system. Addition of Carbopol 974P (CP 974P) to the gelling systems could increase the solubility of ATM by salt effect and enhance the mucoadhesive property of the systems. Gelation temperature of these systems ranged from 31.21-36.31 degrees C depending on the ratio of P407 and P188. Mucoadhesion force of the system composed of P407/P188/CP 974P (21/5/0.3%, w/v) was 2.3-fold that without carbopol 974P. The formulation exhibited a 24-h sustained release of ATM.

Shastri DH et al\(^11\), formulated an in situ gelling thermoreversible mucoadhesive gel of an antibacterial agent, Moxifloxacin HCl using a combination of poloxamer 407 and poloxamer 188 with different mucoadhesive polymers such as Xanthan gum and Sodium alginate with a view to increase gel strength and bioadhesion force and thereby increased precorneal contact time and bioavailability of the drug. Formulations were found transparent, uniform in consistency and had good spreadability within a pH range of 6.8 to 7.4. The order of drug release was in order: Xanthan gum > Sodium alginate.

Bhowmik M et al\(^12\), studied effect of salts on gelation and drug release profiles of methylcellulose-based ophthalmic
thermo-reversible in situ gels. The gel temperature of 1% w/v methylcellulose (MC) was 60 degrees C. It was found that 5-7% w/v sodium chloride (NaCl), 8-9% w/v potassium chloride (KCl), or 5% w/v sodium bicarbonate (NaHCO3) was capable of decreasing the gel temperature below physiological temperature, i.e. 37 degrees C. It can be concluded that the salted MC solutions were a better alternative than the MC solution to enhance the ocular bioavailability of the drug.

Liu Y et al15, studied in situ gelling gelrite/alginate formulations as vehicles for ophthalmic drug delivery of matrine. It was found that the optimum concentration of Gelrite solution for the in situ gel-forming delivery systems was 0.3% (w/w) and that for alginate solution was 1.4% (w/w). The mixture of 0.2% Gelrite and 0.6% alginate solutions showed significant enhancement in gel strength at physiological condition. In vivo pharmacological studies indicated that the Gelrite/alginate solution had the better ability to retain drug than the Gelrite or alginate solutions alone.

Gratieri T et al16, formulated a poloxamer/chitosan in situ forming gel with prolonged retention time for ocular delivery. The results showed that chitosan improves the mechanical strength and texture properties of poloxamer formulations and also confers mucoadhesive properties in a concentration-dependent manner. After a 10-min instillation of the poloxamer/chitosan 16:1 formulation in human eyes, 50-60% of the gel was still in contact with the cornea surface, which represents a fourfold increased retention in comparison with a conventional solution.

Gupta S et al17, studied dual-drug delivery system based on in situ gel-forming nanosuspension of forskolin to enhance antiglaucoma efficacy. By formulating NovoNeon AA-1 polycarbophil/poloxamer 407 platforms, at specific concentrations, it was possible to obtain a pH and thermoreversible gel with a pH(gel)/T (gel) close to eye pH/temperature. Investigations successfully prove that the pH and thermoreversible polymeric in situ gel-forming nanosuspension with ability of controlled drug release exhibits a greater potential for glaucoma therapy.

Al-Kassas RS et al18, developed ophthalmic controlled release in situ gelling systems for ciprofloxacin based on polymeric carriers. Carbopol and alginites polymers were used to confer gelation properties to the formulations. Hydroxypropylmethylcellulose and methylcellulose were combined with carbopol to increase the viscosity of the gels and to reduce the concentration of the incorporated carbopol.

Singh SR et al19, used L-Carnosine: multifunctional dipeptide buffer for sustained-duration topical ophthalmic formulations. Specific utilisation of L-carnosine as a buffer in gelan gum carrying vehicles was characterised. Combinations of 7.5 mm L-carnosine with 0.06-0.6% (w/v) gelan gum were characterized rheologically. A unique formulation combining timolol (which lowers intraocular pressure) in L-carnosine-buffered gelan gum was compared with Timoptic-XE.

Functional synergy between excipients in gelan gum formulations buffered with L-carnosine has potential for topical ocular dosage forms with sustained precorneal residence.

Mayol L et al18, studied the influence of hyaluronic acid (HA) on the gelation properties of poloxamers blends with the aim of engineering thermosensitive and mucoadhesive polymeric platforms for drug delivery. The optimised systems were loaded with acyclovir and its release properties studied in vitro. By formulating poloxamers/HA platforms, at specific concentrations, it was possible to obtain a thermoreversible gel with a T(gel) close to body temperature. In vitro release experiments indicated that the optimized platform was able to prolong and control acyclovir release for more than 6h.

Mansour M et al19, developed ocular poloxamer-based ciprofloxacin hydrochloride in situ forming gels. The in situ forming gels were prepared using different concentrations of poloxamer 407 (P407) and poloxamer 188 (P188). Mucoadhesives such as hydroxypropylmethyl cellulose (HPMC) or hydroxyethyl cellulose (HEC) were added to the formulations to enhance the gel bioadhesion properties. Ciprofloxacin HCl in situ forming gel formulae composed of P407/P188/HPMC (18/13/1.5%, wt/wt), and P407/P188/HEC (18/13/0.5%, wt/wt) showed optimum release and mucoadhesion properties and improved ocular bioavailability as evidenced by an enhanced therapeutic response compared with the marketed conventional eye drops.

Jain SP et al20, formulated in situ ophthalmic gel of ciprofloxacin hydrochloride for once a day sustained delivery. The in situ gelling system involves the use of polycrylic acid (Carbopol 980NF) as phase transition polymer, hydroxypropyl methylcellulose (Methocel K100LV) as a release retardant, and ion exchange resin as a complexing agent. Ciprofloxacin hydrochloride was complexed with ion exchange resin to avoid incompatibility between drug and polycrylic acid. The developed formulation was stable, and nonirritant to rabbit eyes and in vitro drug release was found to be around 98% over a period of 24 hours.

Ma WD et al21, studied temperature-responsive, Pluronic-g-poly(acrylic acid) copolymers in situ gels for ophthalmic drug delivery. The in vivo experimental results, along with the rheological properties and in vitro drug release studies, demonstrated that in situ gels containing Pluronic-g-PAA copolymer may significantly prolong the drug resident time and thus improve bioavailability. The results showed that the Pluronic-g-PAA copolymer can be a promising in situ gelling vehicle for ophthalmic drug delivery.

Liu Z et al22, studied ocular pharmacokinetics of ion-activated in situ gelling ophthalmic delivery system for gatifloxacin by microdialysis. The conventional ophthalmic solution of gatifloxacin was used as reference. The developed formulation has a higher bioavailability...
and longer residence time in aqueous humor than conventional ophthalmic solutions.

Gupta H et al\textsuperscript{22}, described formulation and evaluation of an ocular delivery system of timolol maleate based on the concept of both temperature and pH-triggered in situ gelation. Pluronic F-127 (a thermosensitive polymer) in combination with chitosan (pH-sensitive polymer also acts as permeation enhancer) was used as gelling agent. Developed formulation was clear, isotonic solution that converted into gel at temperatures above 35 degrees C and pH 6.9-7.0. The developed system is a viable alternative to conventional eye drops for the treatment of glaucoma and various other ocular diseases.

Cao Y et al\textsuperscript{26}, investigated a novel copolymer, poly(N-isopropylacrylamide)-chitosan (PNIPAAm-CS), for its thermosensitive in situ gel-forming properties and potential utilization for ocular drug delivery. The in vivo ocular pharmacokinetics of timolol maleate in PNIPAAm-CS solution were evaluated and compared to that in conventional eye drops using rabbits according to the microdialysis method. Results suggest that PNIPAAm-CS is a potential thermosensitive in situ gel-forming material for ocular drug delivery, and it may improve the bioavailability, efficacy, and compliance of some eye drugs.

Liu Z et al\textsuperscript{25}, studied an alginate/HPMC-based in situ gelling ophthalmic delivery system for gatifloxacin. Alginate (Kelton) was used as the gelling agent in combination with HPMC (Methocel E50Lv) which acted as a viscosity-enhancing agent. Both in vitro release studies and in vivo pre-corneal retention studies indicated that the alginate/HPMC solution retained the drug better than the alginate or HPMC E50Lv solutions alone. These results demonstrate that the alginate/HPMC mixture can be used as an in situ gelling vehicle to enhance ocular bioavailability and patient compliance.

Yoo MK et al\textsuperscript{24}, studied release of ciprofloxacin from chondroitin 6-sulfate-graft-polyoxamer hydrogel in vitro for ophthalmic drug delivery. The bioadhesive and thermally gelling of these graft copolymers will be expected to be an excellent drug carrier for the prolonged delivery to surface of the eye.

Lin HR et al\textsuperscript{27}, prepared in situ gelling of alginate/pluronic solutions for ophthalmic delivery of pilocarpine. The optimum concentration of alginate solution for the in situ gel-forming delivery systems was 2% (w/w) and that for Pluronic solution was 14% (w/w). The mixture of 0.1% alginate and 14% Pluronic solutions showed a significant increase in gel strength in the physiological condition; this gel mixture was also found to be free flowing at pH 4.0 and 25 degrees C. Both in vitro release and in vivo pharmacological studies indicated that the alginate/Pluronic solution retained pilocarpine better than the alginate or Pluronic solutions alone.

Balasubramaniam J et al\textsuperscript{23}, developed an ophthalmic delivery system of the NSAID indomethacin, based on the concept of ion activated in situ gelation. Gelrite gellan gum, a novel ophthalmic vehicle, which gels in the presence of mono or divalent cations present in the lacrimal fluid, was used as the gelling agent. The developed formulations were therapeutically efficacious (in a uveitis induced rabbit eye model) and provided sustained release of the drug over an 8-hour period in vitro.

El-Kamel AH et al\textsuperscript{29}, developed Pluronic F127 (PF127) based formulations of timolol maleate (TM) aimed at enhancing its ocular bioavailability. The effect of isotonicity agents and PF127 concentrations on the rheological properties of the prepared formulations was examined. In an attempt to reduce the concentration of PF127 without compromising the in situ gelling capabilities, various viscosity enhancing agents were added to PF127 solution containing 0.5% TM. The viscosity of formulations containing thickening agents was in the order of PF-MC 3%>PF-HPMC 2%>PF-CMC 2.5%>PF127 15%. The slowest drug release was obtained from 15% PF127 formulations containing 3% methylcellulose.

Miyazaki S et al\textsuperscript{30}, formed in situ gelling xylolucan formulations for sustained release ocular delivery of pilocarpine hydrochloride. In vitro release of pilocarpine from gels formed by warming xylolucan sols (1.0, 1.5 and 2.0% w/w) to 34 degrees C followed root-time kinetics over a period of 6 h. The degree of enhancement of miotic response following sustained release of pilocarpine from the 1.5% w/w xylolucan gel was similar to that from a 25% w/w Pluronic F127 gel.

Srividya B et al\textsuperscript{21}, described sustained ophthalmic delivery of ofloxacin from a pH triggered in situ gelling system. Polyacrylic acid (Carbopol 940) was used as the gelling agent in combination with hydroxypropylmethylcellulose (Methocel E50LV) which acted as a viscosity enhancing agent. The developed formulation was therapeutically efficacious, stable, non-irritant and provided sustained release of the drug over an 8-hour period. The developed system is thus a viable alternative to conventional eye drops.

Lin HR et al\textsuperscript{22}, developed and characterized a series of carbopol- and pluronic-based solutions as the in situ gelling vehicles for ophthalmic drug delivery. It was found that the optimum concentration of carbopol solution for the in situ gel forming delivery systems was 0.3% (w/w), and that for pluronic solution was 14% (w/w). The mixture of 0.3% carbopol and 14% pluronic solutions showed a significant enhancement in gel strength in the physiological condition; this gel mixture was also found to be free flowing at pH 4.0 and 25 degrees C. The results demonstrated that the carbopol/pluronic mixture can be used as an in situ gelling vehicle to enhance the ocular bioavailability.
CONCLUSION

The development of ophthalmic drug delivery systems is easy because we can easily target the eye to treat ocular diseases and complicated at the same time because the eye has specific characteristics, which make the development of ocular drug delivery systems extremely difficult. The most widely developed drug delivery system is represented by the polymeric hydrogels. In situ activated gel-forming systems see to be preferred as they can be administered in drop form and create significantly less problems with vision. Moreover, they provide good sustained release properties. Over the last decades, an impressive number of novel temperature, pH, and ion induced in situ forming solutions have been described in the literature. Each system has its own advantages and drawbacks. The choice of a particular hydrogel depends on its intrinsic properties and envisaged therapeutic use.
